Abstract. The giant panda (*Ailuropoda melanoleuca*) and golden takin (*Budorcas taxicolor bedfordi*) are large endangered species that coexist within the southern Qinling Mountains, China. Here, we determined the coexistence mechanisms for these sympatric species by investigating microhabitat selection from May to July and from September to November 2009 in a nature reserve. Our results suggested that each species has a distinct microhabitat selection pattern. We found that abiotic factors (elevation and slope) and biotic factors (bamboo cover, density and herb-cover proportion) are simultaneously responsible for microhabitat separation between giant pandas and golden takins during the summer and the winter. We inferred that pattern of microhabitat separation is influenced by diet, migration time, the annual phenological cycle of food resources, energy expenditure and metabolic requirements. Appropriate conservation strategies should not only focus on giant panda protection, but also be extended to encompass the protection of sympatric species. Our study has significant implications for biodiversity conservation across large tracts of China.

Key words: *Ailuropoda melanoleuca*, *Budorcas taxicolor bedfordi*, sympatric species, microhabitat separation, conservation implications.

Introduction

Ecologists have long been interested in the mechanisms that allow the coexistence of sympatric species (Schoener 1974, Diamond & Case 1986). Closely related sympatric species usually share similar potential niches or have similar life history traits. For example, how species compete for similar resources when distributed in overlapping areas or how they avoid competition remain challenging questions. Previously, researchers have attempted to explain the coexistence mechanisms of species through the measurement of abiotic and biotic factors (Werner 1977, Gotelli 1997, Qi et al. 2009).

Giant pandas (*Ailuropoda melanoleuca*) and golden takins (*Budorcas taxicolor bedfordi*) are endangered species and sympatric within the southern part of the Qinling Mountains in China (Wu et al. 1990, IUCN 2007, Wang et al. 2010, Zhang et al. 2011, Li et al. 2017). Previous studies have indicated that these species suffer similar environmental pressures and barriers to genetic flow because of habitat loss and fragmentation, poaching and inbreeding depression (Wei et al. 1999, Zeng

et al. 2003, Wei et al. 2015b, Hong et al. 2015, Hong et al. 2016). The giant panda is a highly endangered species in the order Carnivora and with a highly specialized bamboo diet for which it has low digestive efficiency (Zhu et al. 2011, Zhao et al. 2013, Lei et al. 2015, Nie et al. 2015a, Wei et al. 2015a, Wei et al. 2015c). The golden takin is herbivorous with a broad diet that also includes bamboo leaves and shoots (Zeng et al. 2010). These two species may compete for similar food resources during some stages of their life histories. Further, both species engage in seasonal vertical movement in mixed bamboo forest landscapes. Thus, there should be overlapping niches (Wang et al. 2010). Distribution and diet overlap between these species raise the question of whether they share niches and resources via microhabitat partitioning. Previous studies have reported habitat selection and microhabitat utilization for these species in the Qinling Mountains (Song et al. 1995, Liu et al. 2005, Feng et al. 2009, Zhang et al. 2009). However, these studies failed to determine a relationship explaining microhabitat utilization between the two species and factors responsible for microhabitat separation at the microhabitat scale.

To improve our understanding of observed patterns of microhabitat separation between giant pandas and golden takins we investigated patterns of microhabitat preferences in these animals. We aimed to (1) verify whether each species has special microhabitat-selection patterns; (2) describe which factors are responsible for microhabitat separation; and (3) generate an effective strategy for protection of sympatric species and regional biodiversity.

Materials and methods

Study site

We conducted this study in Foping Nature Reserve, Shaanxi, China (Fig. 1). This reserve was established primarily for preserving giant pandas. This region contains the highest density of wild giant pandas in the world (population density = 76) (Administration 2006). The reserve covers 293 km² and the elevation ranges from 980 to 2,904 m above sea level. The annual mean temperature is 11.5°C. Annual mean rainfall is 930 mm and the first snowfall occurs in November on high ridges and about a month later descends to lower altitudes (< 1,500 m). Snow begins to melt in early March and is completely melted at higher ranges by late March. The population of golden

takin was estimated at 435–527 individuals in 1996 (Zeng et al. 1998).

The distribution of vegetation in the study area shows characteristic vertical zonation, with four major forest types: broadleaf deciduous (below 2,000 m), mixed coniferous and deciduous (2,000–2,500 m), coniferous forests (above 2,500 m), and some interspersed subalpine shrubs and meadows at the top of the mountains (above 2,600 m) (Ren et al. 1998). Two bamboo species, *Bashania fargesii* (mean elevation 1,600 m) and *Fargesia qinlingensis* (mean 2,400 m), dominate the forest understory and are the main food resources for giant pandas.

Microhabitat identification

Both species are difficult to observe directly in the field, so feces can be used as an indicator of microhabitat utilization (Wei et al. 2000, Zhang et al. 2004, 2009). Giant panda feces are spindle-shaped (average length by width 14.5 cm × 5.0 cm) and blackish green; golden takin feces are black and resemble large shelled peanuts or fecal mound similar to cattle. Both species' feces are easy to identify and distinguish in the field.

Sampling design and variable measurement

A detailed sampling method firstly used by Dueser and Shugart (1978) considers diverse sizes and shapes and small transects together; which has been proved to be suitable for most terrestrial mammals (Morrison et al. 1992). This sampling method was later developed and modified by Wei et al. (2000) and applied to the research of microhabitat separation of giant pandas and red pandas (*Ailurus fulgens*).

We walked randomly through the habitats with different vegetation types within the reserve to search for signs of each species and fresh feces in 2009. The presence of giant panda and golden takin were determined primarily by fresh feces. Once a fresh fecal group was found, the following were established: a 20 m × 20 m sampling plot was built and centred on the fecal location; one 1.0 m² bamboo plot at the centre of each 20 m × 20 m plot; and two 20 m² rectangular transects (each 2 m × 10 m) were set within the 20 m × 20 m plot. The two 20 m² rectangular transects were perpendicular to each other, and their diagonals crossed at the location of the feces. Each side of the rectangular transect was parallel to the corresponding side of the 400 m² square plot (Wei et al. 2000, Zhang et al. 2004). The minimum distance among microhabitat plots was not less than 100 m. To establish control plots, we randomly located points on slopes in our study area, which were equally distant from each other, and established 15 transects from these points. Twenty-two microhabitat variables were measured (Table 1). In total, we had sampled 44 habitat plots of giant panda, 46 habitat plots of golden takin and 80 control plots, respectively, in the summer. Moreover, we had sampled 17 habitat plots of giant panda, 27 habitat plots of golden takin and 58 control plots in the winter.

Data analysis

We used the Kruskal-Wallis test to compare means for all 22 variables among the two species and control group.

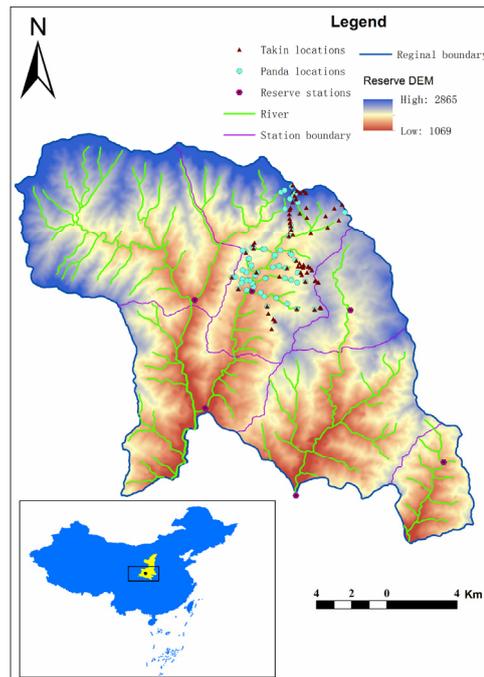

Figure 1. Giant panda and golden takin distribution locations acquired from feces in Foping Nature Reserve, DEM shown corresponds with elevation range in the study area

Table 1. The variables used in this research.

Variables	Description
Altitude	Altitude of each 20 × 20 m plot
Slope	Slope of the 20 × 20 m plot range from 0° to 90°; divide into 6 categories: every 15° is a category; measured with a gradiometer
Slope aspect	Aspect of the each 20 × 20 m plot; divide into categories: towards east (45–135°), towards south (135–225°), towards west (225–315°), and towards north (315–45°)
Vegetation type	Six type: shrub, deciduous broadleaf forest, mixed conifer and broadleaf forest, conifer forest, grassland, and others
Canopy	Canopy of overstory in each 20 × 20 m plot, defined as 5 categories: <20%, 21–40%, 41–60%, 61–80% and >81%
Tree density (no./m ²)	Total tree amount of each 20 × 20 m plot
Tree height (m)	Average height of trees in two 2 × 10 m rectangular transects plots; defined as 5 categories: 5–10 m, 11–15 m, 16–20 m, 21–25 m and >25 m
Tree diameter at breast height (DBH) (cm)	Average DBH of the trees nearest the center in each 10×10 m square plot
Succession phases	Successional changes in plant communities; five type: immature forest, bushwood, secondary forest, mature forest and old forest.
Shrub cover (%)	Coverage of shrub in each 20 × 20 m plot, divided into 5 categories: 0–20%, 21–40%, 41–60%, 61–80% and >81%
Shrub density (no./m ²)	Total shrub amount of each 20 × 20 m plot
Shrub height (m)	Average height of shrubs in two 2 × 10 m rectangular transects plots; defined as 6 categories: <1 m, 1–2 m, 2–3 m, 3–4 m, 4–5 m and 5–6 m
Shrub DBH (cm)	Average DBH of the shrubs nearest the center in each 10 × 10 m square plot
Bamboo forest	Whether have large dense tracts of bamboo forest or not in the 20 × 20 m plot
Bamboo type	The species of bamboo in each 20 × 20 m plot, including <i>B. fargesii</i> and <i>F. qinlingensis</i>
Bamboo cover (%)	Average coverage of bamboo in five 1 × 1 m plot, divided into 5 categories: 0–20%, 21–40%, 41–60%, 61–80% and >81%
Bamboo density (no./m ²)	Average number of culms in five 1 × 1 m bamboo plots
Bamboo height (m)	Average height of culms in five 1 × 1 m bamboo plots; defined as 6 categories: <1 m, 1–2 m, 2–3 m, 3–4 m, 4–5 m and 5–6 m
Herb-cover (%)	Proportion of herb-cover area in each 20 × 20 m plot; five categories: <20%, 21–40%, 41–60%, 61–80%, and >81%
Open-land proportion (%)	Proportion of vacant land area without any plant in each 20 × 20 m plot; five categories: <20%, 21–40%, 41–60%, 61–80%, and >81%
Water-source dispersion (m)	Estimated straight-line distance from the sampling plot to the nearest water source; five categories: 0–100, 101–200, 201–300, 301–400 and >400
Road-path dispersion (m)	Estimated straight-line distance from the sampling plot to the nearest road; five categories: 0–100, 101–200, 201–300, 301–400 and >400

We retained for further analysis only those variables that showed significant differences using this nonparametric test, to provide us with a conservative basis for detecting microhabitat separation.

For those variables showing significant differences, Mann-Whitney U tests were used to compare whether or not significant differences existed among microhabitat plots of giant panda, golden takin and controls. Stepwise discriminant function analysis was used to further analyse microhabitat separation between the two species and to detect the variables primarily responsible. We used Spearman Correlation Analysis to compare correlation coefficients for each two variables. If correlation coefficients exceeded 0.7 we only retained more biological meaningful variables entered for subsequent logistic regression analysis as this eliminates multicollinearity effects (Wei et al. 2000; Zhang et al. 2009). All test were conducted using SPSS v21 (SPSS Inc., Chicago, USA), and the significance level of all analyses was set at 0.05.

Results

Summer habitat separation

The Kruskal-Wallis tests showed that six of 22 variables differed significantly ($P < 0.05$) (Table 2). Mann-Whitney U tests demonstrated that nine variables (elevation, shrub density, bamboo forest, bamboo type, bamboo cover, bamboo height, herb cover, water-source dispersion and road-path dispersion) differed between giant panda and golden takin plots. Giant panda microhabitat plots were at a lower elevation than control plots and golden takin plots (control plots and golden takin plots were at the similar elevation) (Table 3). Similarly, giant pandas preferred habitats with fewer shrubs, taller bamboo, less herb cover and closer to a water source. When comparing giant panda and

golden takin plots, elevation, bamboo cover, herb cover and water-source dispersion had larger absolute discriminant coefficients than other variables (Fig. 2a,b,c), indicating that microhabitat separation mainly results from these four variables (Wilk's Lambda = 0.658, $P < 0.01$; 77.8% of observations classified correctly; Table 4). Similarly, bamboo height and water-source dispersion were mainly responsible for the separation between the giant panda and control plot groups, and herb cover was mainly responsible for separation between golden takin and control plot groups (Table 4). Among variables where the correlation coefficients exceeded 0.7, we excluded biologically meaningless variables (bamboo forest, bamboo type and road-path dispersion), and thus, the

type, bamboo cover, bamboo density, bamboo height, herb cover, open-land, and water-source dispersion. Giant pandas prefer microhabitats that have a lower elevation, gentler slope, southern aspect, broadleaf deciduous forest, a smaller canopy, greater bamboo cover and density, less herb-cover and close to water sources (Fig. 2a,b,c). In contrast, golden takin prefer less bamboo cover, shorter bamboo, more herb-cover and less open-land (Table 3, Fig. 2b). Between microhabitat plots of giant panda and golden takin, bamboo type, bamboo cover and herb cover had larger discriminant coefficients than other variables (Table 4), indicating that microhabitat separation between the two species can be mainly explained by three variables (Wilk's Lambda = 0.292, $P < 0.01$; 94.45% of observations classified correctly). Similarly, elevation, bamboo cover and herb cover were mainly responsible for the separation between giant panda and control plot groups, and herb cover was mainly responsible for that between golden takin and control plot groups (Table 4). Logistic regression analysis showed that bamboo cover, bamboo density and water source dispersion had a greater contribution distinguishing the two species' plots ($\chi^2 = 42.48$, $df = 6$, $P < 0.01$; Table 5), with an overall correct prediction rate of 90.9%.

Discussion

Our results reveal different patterns of microhabi-

tat utilization between two sympatric species in Foping Nature Reserve. Suitable microhabitats should contain abundant resources and favourable topographic conditions essential for individual survival and reproduction where animals can maximize individual fitness. Environmental heterogeneity promotes the coexistence of sympatric species by reducing interspecific competition (Stephanie 2004). Our results show that giant pandas and golden takins prefer different habitats in different seasons. From the late spring to the early summer, giant pandas and golden takins select diverse microhabitats. Unlike golden takin, giant pandas are specialized bamboo feeders, and bamboo resources play a key role in microhabitat selection whereby they prefer bamboo forest with greater cover and density (Fig. 2b). Because bamboo is a low-quality food (Hu et al. 1985, Schaller et al. 1985, Wei et al. 2000, Nie et al. 2015b, Wei et al. 2015c), a strong preference for habitats with high bamboo density can reduce giant panda energy expenditure while searching for forage (Reid & Hu 1991, Zhang et al. 2004). Conversely, the golden takin has a broader diet that includes bamboo and herbs, shrubs and young trees. Our results demonstrate that golden takin prefer habitats with more shrubs, more herb-cover and less bamboo cover (Fig. 2b), consistent with previous research (Zeng et al. 2001). In addition, the two species undergo a regular seasonal large-scale vertical movement (Zeng et al. 2008, Zhang et al. 2014, Nie et al. 2015b, Wei et al. 2015c). The migration from winter habitats (low elevation) to summer habitats (high elevation, >2,000 m) occurs in early spring in golden takins and late spring in giant pandas (Wang et al. 2010). Our results confirm the divergence in elevation between the two species (Fig. 2a), suggesting that giant pandas move to higher elevations later than golden takins. The seasonal migration of giant pandas is driven by the annual bamboo cycle. In Foping Nature Reserve there are two main bamboo species (*B. fargesii* and *F. qinlingensis*) consumed by giant pandas (Nie et al. 2015b, Wei et al. 2015c). The shooting season of *B. fargesii* occurs in early May, and peaks in late May; the shooting season of *F. qinlingensis*, occurs from the mid-June to the end of July and peaks in July (Pan et al. 1988). The shoots of *F. qinlingensis* are available when giant pandas move up to summer habitats in mid-June. In contrast, because golden takin are generalists, the phenological change in their forage is not completely influenced by the bamboo cycle. Once alpine vegetation begins to

sprout in May to July, they ascended to high altitudes at the beginning of May (Zeng et al. 2008, 2010). Thus, golden takins occupy a higher elevation niche ($2,015 \pm 259$ m) than giant pandas ($1,849 \pm 288$ m) from the spring to the summer. Giant pandas also prefer microhabitats closer to water than golden takin in the summer (Fig. 2c), perhaps because bamboo shoots sprout earlier and are of better quality in areas closer to rivers and streams.

The giant panda and golden takin return to winter habitats in early autumn. The migration time of giant pandas is earlier than golden takin (Wang et al. 2010). As the shoots of *F. qinlingensis* lignify seriously in August, giant pandas have to switch to eat leaves and stems of *F. qinlingensis*. And *B. fargesii* begins to sprout new leaves at low elevations later, so giant pandas gradually move down to winter habitats. Meanwhile, the weather becomes colder and the decline in forage quality and quantity at high elevations forces golden takins to move down to search for food in late autumn. Microhabitat separation of the two species is significant in winter habitats: giant pandas prefer gentler slopes and dense bamboo forests at lower elevations, whereas golden takin prefer higher herb cover and less open-land as this maximizes energy net income and reduces energy expenditure. Our data indicate that giant pandas remain close to rivers and streams during the autumn and the winter, perhaps because of the increasing requirements of water when digesting high-fibre food (Hu et al. 1985, Zhang et al. 2014).

Sympatric species show differences in at least one spatial dimension to decrease excessive interspecific competition and coexist harmoniously, including feeding sites, dietary habits, microhabitat utilization, activity rhythm and day roosts (Honer 1982, Wei et al. 2000, Siemers & Swift 2006, Campbell et al. 2007, Jacobs & Barclay 2009, Jiang et al. 2013). Microhabitat separation is regarded as the most common form of niche partitioning in sympatric mammals. Microhabitat separation is contributing to multiple-species coexistence (Schoener 1982, Marsh & Harris 2000, Sébastien et al. 2003). Our results suggest that giant pandas and golden takin display different microhabitat selection patterns although they appear to have overlapping activity ranges during part of the year. This partitioning of specific microhabitats between the two species may reflect an ecological adaptation directly related to dietary habits, annual phenological cycles of food resources, migration patterns, energy expenditure and metabolism requirements,

ensuring their survival and reproduction by minimizing interspecific competition (Grether et al. 2009).

It has been generally accepted that giant panda is an umbrella for other sympatric animals and once its habitat is conserved, other species in the same habitats will be protected (Zhang et al. 2006, Li & Pimm 2015). However, our results reveal that these sympatric species have distinct microhabitat-selection patterns and that if we only consider the protection of giant panda habitats, we will fail to protect key habitats for non-targeted species such as golden takin (also see Kang et al. 2013). We think such these two significant different results were probably caused by different spatial scales. Habitat selection is a spatial scale-dependent ecological process (Morris 1992, Eloy et al. 2000). Co-occurring other species can be well protected under the conservation of giant panda in landscape scale or regional scale. By contrast, our research had concentrated upon a small microhabitat scale. Thus, based on microhabitat selection scale, we suggest that specific approaches are needed to conserve understory bamboo forests, alpine shrub and meadows related to the dietary habits, annual phenological cycle and migration patterns of sympatric species. Conservation approaches combining surrogate species protection with non-target species protection will provide a broader and stronger conservation platform to enhance biodiversity conservation.

Acknowledgements. This project was supported by the National Natural Science Foundation of China (31270570), and International Cooperation Foundation for Giant Pandas of the State Forestry Administration (CM 1425). We would like to thank X.M. Zhou for comments on this manuscript. X.L. Wang, A.X. Zhang, J.L. Pu and C.D. Li assisted in the field. Foping Nature Reserve Administration Bureau provided a great deal of assistance. We also thank the two anonymous reviewers for their constructive comments.
